Statistics (Notes)

Mark DiBattista

February 6, 2020

Abstract

Statistics is a branch of probability theory that addresses questions of probabilistic modeling, usually the suitability of a hypothesized distribution or the presence/absence of a specific distributional property for a given set of measurements. Since statistics are simply functions of random variables, they are themselves random variables to which the tools of probability theory can be applied. There is however, a difference in emphasis between the two: probability theory is mainly concerned with analytical properties of parametrized functions, whereas statistics, with its attendant specialized vocabulary, mainly addresses consistency of hypothesized distributions or unknown parameters with randomly sampled data.

2 Statistics Preliminaries

2.1 Nomenclature

Given random variables, X and Y

Probability	$\mathbb{P}X$	PN $\S 2.1.6$
Expectation	$\mathbb{E}X$	PN $\S 2.1.10$
Variance	$\mathbb{V}X$	PN $\S 3.1$
Covariance	$\mathbb{C}(X,Y)$	PN $\S 3.2$
Fisher Information	$\mathbb{I}_F X$	PN $\S 10.4.2$

2.2 Terms and Definitions

2.2.1 Basic Definitions/Setting

The basic probabilistic setting for the study of parametrized models – a major branch of statistics – consists of the following items:

- Uncertainty in a physical quantity or process is modeled by a random variable, frequently governed by an unknown parameter, represented as $X|\theta$;
- A sequence of measurements of the underlying quantity or process is modeled by a random vector, $\mathbf{X} = (X_1, \dots, X_n), X_i \sim X \equiv X | \theta$, for which each coordinate follows the common parametrized distribution. Should each coordinate measurement be assumed independent of the others independently and identically distributed (IID) then the covariance of distinct coordinates vanishes, $\mathbb{C}(X_i, X_j) = 0, i \neq j$.
- The specific vector of data points generated by measurement is represented in lower case, \mathbf{x} , and observations enter into statistical analyses through the condition, $\mathbf{X} = \mathbf{x}$;
- A statistic is any function of a random variable, usually a random vector, $T(\mathbf{X})$. A test statistic is one designed for quantitative inference about the values or properties of the underlying population model. The population and measured properties are linked through the test statistic, which is itself a random variable, and the probability distribution that it generates;
- Assertions on population properties are evaluated from the expected probabilities of observed test statistics, given the proposed underlying models.

2.2.2 Statistical Operations

The specification of an underlying population distribution, $X|\theta$, is a modeling choice. Sample data, $\mathbf{X} = \mathbf{x}$, is generated through physical measurement. Statistics, the mathematical branch, links measurement to model, using functions of sample data, $T(\mathbf{X})$, to assess proposed values for the parameter, or any other asserted property of the underlying population. There are two distinct types of analyses commonly run:

- **Point Estimation:** Given a random sample, $\mathbf{X} = \mathbf{x}$, and an explicit metric, provide the best estimate for the parameter, θ , that governs the distribution;
- Interval Testing: Given a hypothetical value for the parameter, θ , or an assertion that the random coordinates are independent, estimate the probability that the random sample, $\mathbf{X} = \mathbf{x}$, falls within a specified range. Hypotheses may be rejected if the realized measurement is deemed sufficiently improbable.

Point estimators and interval tests are based on *test statistics*, $T(\mathbf{X})$, which, as functions of random variables, are themselves random variables. The first and second moments of the distribution associated with the test statistic provide quantitative information on the estimator, and are assigned characteristic terminology:

• The bias of a point estimator is given by the mean of the difference between true value and test statistic:

$$\mathbb{B}T(\mathbf{X}) = \mathbb{E}\left(T(\mathbf{X}) - \theta\right);\tag{1}$$

• The **mean-squared error** of a point estimator is given by the variance of the difference between true value and test statistic:

$$MT(\mathbf{X}) = \mathbb{E}\left(T(\mathbf{X}) - \theta\right)^2 = VT(\mathbf{X}) + (BT(\mathbf{X}))^2.$$
(2)

There are two standard kinds of optimality for point estimators for a given parameter, expressed in terms of bias and mean-squared error:

- The Minimum-Variance Unbiased Estimator (MVUE) has the least mean-squared error among all estimators with no bias;
- The Minimum Mean-Squared Error (MMSE) has the least mean-squared error among all estimators.

It is frequently the case that, for point estimators, small increases in bias can be traded for significant reduction in mean-squared error.

2.2.3 Properties of Point Estimators

Point estimators based on test statistics are differentiated by a number of properties:

• An **unbiased statistic** is one for which the bias is zero,

$$\mathbb{B}T(\mathbf{X}) = 0; \tag{3}$$

A sufficient statistic is one that contains all information necessary to estimate the parameter,
 θ. In quantitative terms this is expressed as absence of the parameter in the distribution of data conditioned on the test statistic:

$$p_{\mathbf{X}:\theta|T(\mathbf{X})}(\mathbf{x};\theta|t(\mathbf{x})) = h(\mathbf{x}). \tag{4}$$

Given the value of the statistic, $T(\mathbf{X})$, no additional information is afforded by the parameter, θ . A necessary and sufficient condition is given by the **Fisher-Neyman Theorem**:

$$p(\mathbf{X}|\theta) = h(\mathbf{X})q(\theta, T(\mathbf{X})) \Leftrightarrow T(\mathbf{X}) \text{ is a sufficient statistic,}$$
 (5)

which is proven by executing a change of variable from the space of data into a space of statistics, only one of which (the test statistic) depends on the parameter. The partition of the joint distribution, $p_{\mathbf{X}}|\theta$, into marginal and conditional components with the required properties follows immediately. Note that the form of the exponential family of distributions – cf. PN, §7.4 – explicitly references a sufficient statistic, and is one for which the parameter and statistic are simple multiples that form the exponential argument.

 A complete statistic is one for which distinct parameters govern different probability distributions:

$$\mathbb{E}_{\theta}g(T(\mathbf{X}) = 0 \Rightarrow \mathbb{P}_{\theta}\{g(T(\mathbf{X}) = 0\} = 1.$$
(6)

Completeness of a statistic is essentially identical to the *identifiability* of a statistical model.

These notions are united in the **Lehmann-Scheffé theorem**: an unbiased, sufficient and complete statistic is the unique MVUE for the parameter.

2.2.4 Asymptotic Properties of Statistics

Given an increasing vector of random variables, $\mathbf{X}_n = (X_1, \dots, X_n), X_i \sim X$, for which each element in the series is sampled from the same parametrized distribution, $X \equiv X | \theta$, and a matching sequence of statistics, $T(\mathbf{X}_n)$, we have the following statistical analogs to the law of large numbers and central limit theorem:

• A consistent statistic converges in probability to the true parameter value,

$$T(\mathbf{X}_n) \xrightarrow{p} \theta$$
 (7)

• An **asymptotically normal statistic** converges in distribution to a Gaussian with variance decreasing in proportion to the square-root of the number of samples,

$$\sqrt{n}(T(\mathbf{X}_n) - \theta) \xrightarrow{d} N(0, \sigma^2)$$
 (8)

3 Point Estimation

Following the terminology introduced above in §2.2.1, a **point estimator** for a model parameter is a sample statistic derived from the IID joint distribution,

$$\mathbf{X} = (X_1, \dots, X_n), X_i \sim X \equiv X | \theta \Rightarrow T(\mathbf{X}) \approx \theta,$$
 (9)

that serves to approximate the parameter. A point estimator is therefore a random variable, governed by a probability distribution, and with full rights to all other properties afforded by probability theory.

The **efficiency** of a point estimator is a measure of its variance in comparison to all other point estimators of the same parameter. The *most efficient* point estimator has least variance.

3.1 Cramer-Rao Lower Bound

The theoretical minimum variance for unbaised point estimators is provided by the **Cramer-Rao lower** bound: given a point estimator for the parameter,

$$\left. \begin{array}{l} \mathbf{X}_{\theta} = (X_1, \cdots, X_n), X_i \sim X \equiv X | \theta \\ \mathbb{B}T(\mathbf{X}_{\theta}) = 0 \end{array} \right\} \Rightarrow \mathbb{V}T(\mathbf{X}_{\theta}) \ge \frac{1}{\mathbb{I}_F \mathbf{X}_{\theta}}, \tag{10}$$

the theoretical minimum possible variance across all possible statistics is provided by the reciprocal of the Fisher information (cf. PN, §10.4.2). The Cramer-Rao lower bound provides the variance for the MVUE.

For arbitrary statistics, not necessarily unbiased, the Cramer-Rao lower bound is proportional to a function of the expectation of the statistic:

$$VT(\mathbf{X}_{\theta}) \ge \frac{\left(\frac{\partial}{\partial \theta} \mathbb{E}T(\mathbf{X}_{\theta})\right)^{2}}{\mathbb{I}_{F}\mathbf{X}_{\theta}}.$$
(11)

The derivation of the Cramer-Rao theorem follows directly from the application of the Cauchy-Schwarz inequality (cf. PN, §4.1) to the covariance of the score function (again cf. PN, §10.4.2), $S(\theta|\mathbf{X})$, and the statistic, $T(\mathbf{X})$. Given the covariance,

$$\mathbb{C}(S(\theta|\mathbf{X}_{\theta}), T(\mathbf{X}_{\theta})) = \mathbb{E}S(\theta|\mathbf{X}_{\theta})T(\mathbf{X}_{\theta}) - \mathbb{E}S(\theta|\mathbf{X}_{\theta}) \cdot \mathbb{E}T(\mathbf{X}_{\theta}) = \mathbb{E}S(\theta|\mathbf{X}_{\theta})T(\mathbf{X}_{\theta})$$

$$= \int_{D} p(\mathbf{x}|\theta)T(\mathbf{x})\frac{\partial}{\partial \theta} \ln p(\mathbf{x}|\theta) d\mathbf{x} = \int_{D} T(\mathbf{x})\frac{\partial}{\partial \theta}p(\mathbf{x}|\theta) d\mathbf{x} = \frac{\partial}{\partial \theta}\mathbb{E}T(\mathbf{X}_{\theta}), \tag{12}$$

the Cauchy-Schwarz inequality yields

$$\mathbb{V}(S(\theta|\mathbf{X}_{\theta}) \cdot \mathbb{V}T(\mathbf{X}_{\theta}) \ge (\mathbb{C}(S(\theta|\mathbf{X}_{\theta}), T(\mathbf{X}_{\theta})))^{2} \Rightarrow \mathbb{V}T(\mathbf{X}_{\theta}) \ge \frac{(\mathbb{C}(S(\theta|\mathbf{X}_{\theta}), T(\mathbf{X}_{\theta})))^{2}}{\mathbb{V}(S(\theta|\mathbf{X}_{\theta}))} = \frac{\left(\frac{\partial}{\partial \theta} \mathbb{E}T(\mathbf{X}_{\theta})\right)^{2}}{\mathbb{I}_{F}\mathbf{X}_{\theta}}.$$
(13)

3.2 Rao-Blackwell Theorem

Given a distribution parametrized by θ , the variance of any arbitrary estimator, $U(\mathbf{X})$, does not increase – and often improves – by conditioning the estimator with a sufficient statistic, $T(\mathbf{X})$. Defining the estimators,

$$\hat{\theta} = \mathbb{E}_{\theta}(U(\mathbf{X})) \tag{14}$$

$$\theta^* = \mathbb{E}_{\theta}(\hat{\theta}|T(\mathbf{X})) \tag{15}$$

the variance of the conditioned estimator is never larger,

$$\mathbb{E}_{\theta}(\theta^* - \theta)^2 = \mathbb{E}_{\theta}(\mathbb{E}_{\theta}(\hat{\theta}|T(\mathbf{X}) - \theta)^2) = \mathbb{E}_{\theta}(\mathbb{E}_{\theta}(\hat{\theta} - \theta|T(\mathbf{X}))^2 \le \mathbb{E}_{\theta}(\mathbb{E}_{\theta}((\hat{\theta} - \theta^2|T(\mathbf{X}))) = \mathbb{E}_{\theta}(\hat{\theta} - \theta)^2.$$
(16)

3.3 Methods for Generating Point Estimators

There are three common bases upon which point estimators are constructed for distribution parameters given a sequence of data points:

- the *sample moments* of the data points, for which the moments of the distribution are linked through a system of equations;
- the maximum likelihood of the sample distribution given the data points, for which the Shannon information is leveraged;
- the Bayes' risk of the sequence of sample distributions, for which an informed prior can be assigned.

3.3.1 Point Estimators for Moments

Given a random vector of data points, each sampled independently from the same distribution, we can generate the random vector of moments by simple averages of samples:

$$\mathbf{X} = (X_1, \cdots, X_n), X_i \sim X \Rightarrow \begin{cases} \vdots \\ S_n^j = \frac{1}{n} \sum_{i=1}^n X_i^j \\ \vdots \end{cases}$$
 (17)

which shows an arbitrary element of the random moment vector, $\mathbf{S}_n = (S_n^1, \dots, S_n^n)$, constructed from the first n data points.

Assigning the subscripted symbol to the expectation of the sample moment

$$\mu_i = \mathbb{E}X^i = \mathbb{E}S_n^i \tag{18}$$

the equivalence of moments is guaranteed by linearity of the averaging operator and the law of large numbers (cf. PN, $\S 9.2.1$), and the covariance matrix of sample moments is expressed as simple combinations of sample expectations,

$$\mathbb{C}(S_n^i, S_n^j) = \mathbb{E}(S_n^i - \mathbb{E}S_n^i)(S_n^j - \mathbb{E}S_n^j) = \mathbb{E}S_n^i S_n^j - \mathbb{E}S_n^i \mathbb{E}S_n^j = \mathbb{E}S_n^{i+j} - \mathbb{E}S_n^i \mathbb{E}S_n^j$$

$$= \mu_{i+j} - \mu_i \mu_j. \quad (19)$$

3.3.2 Method of Moments

Given a random variable, X, parametrized by a vector, $\boldsymbol{\theta} = (\theta_1, \dots, \theta_k)^{\top}$, the information in the distribution is reduced to an independent system of equations of moments that are functions of the parameters alone:

$$\mu_1 = \mathbb{E}X = g_1(\theta_1, \dots, \theta_k)$$

$$\vdots$$

$$\mu_k = \mathbb{E}X^k = g_k(\theta_1, \dots, \theta_k)$$
(20)

And given a set of data points, $\mathbf{x} = (x_1, \dots, x_n)$, the true moments are replaced with sample values, $\mathbf{s}_n = (s_n^1, \dots, s_n^k)$,

$$s_n^j = \frac{1}{n} \sum_i x_i^j \Rightarrow \begin{cases} \mathbb{E}X \approx s_n^1 = g_1(\hat{\theta}_1, \dots, \hat{\theta}_k) \\ \vdots \\ \mathbb{E}X^k \approx s_n^k = g_k(\hat{\theta}_1, \dots, \hat{\theta}_k) \end{cases}$$
(21)

from which estimators, $\hat{\boldsymbol{\theta}} = (\hat{\theta}_1, \dots, \hat{\theta}_k)^{\top}$, are inferred through the inverse relation,

$$\mathbf{s}_n = \mathbf{g}(\hat{\boldsymbol{\theta}}) \Rightarrow \hat{\boldsymbol{\theta}} = \mathbf{g}^{-1}(\mathbf{s}_n).$$
 (22)

If \mathbf{g}^{-1} is differentiable at the point, $\boldsymbol{\mu} = (\mu_1, \dots, \mu_k)^{\top}$, and $\mathbb{E}|X|^{2k} < \infty$, then $\hat{\boldsymbol{\theta}}$ is an asymptotically normal estimator for $\boldsymbol{\theta}$, since by the delta method (cf. PN, §9.2.2.2),

$$\sqrt{n}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}) \stackrel{d}{\longrightarrow} N(\mathbf{0}, (J_{\boldsymbol{\mu}}\mathbf{g}^{-1}(\boldsymbol{\mu}))^{\top} \boldsymbol{\Sigma} (J_{\boldsymbol{\mu}}\mathbf{g}^{-1}(\boldsymbol{\mu})), \quad \Sigma_{ij} = \mu_{i+j} - \mu_i \mu_j.$$
 (23)

3.3.3 Maximum-Likelihood Estimators

The method of maximum likelihood is based on properties of **Shannon information**, covered in PN, §10. The method is based on the log-likelihood function,

$$\mathbb{I}_{S} \mathbf{X}_{\theta} \equiv \ln L(\theta | \mathbf{X}) \to \ln p(\mathbf{x} | \theta), \tag{24}$$

for which emphasis is shifted from the probability domain of unknown data points with known parameter to the statistics domain of known data points and unknown parameter. The gradient of the log-likelihood function with respect to the parameter is a random variable known as the **score function**, whose expectation vanishes and whose variance is defined as **Fisher information**:

$$S(\theta|\mathbf{X}) = \frac{\partial}{\partial \theta} \ln L(\theta|\mathbf{X}) \Rightarrow \begin{cases} \mathbb{E}_{\theta} S(\theta|\mathbf{X}) = 0\\ \mathbb{V}_{\theta} S(\theta|\mathbf{X}) \equiv \mathbb{I}_{F} \mathbf{X}_{\theta} \end{cases}$$
(25)

The method of maximum likelihood asserts that the most-probable estimate for the parameter given the measured data is the extremum of the score function. Asymptotic properties, as well as specific numeric methods for calculating estimates, are determined by the moments defined in (25).

3.3.3.1 Univariate Maximum-Likelihood Estimators

Given an admissible set of parameters, $\theta \in \Theta$, the maximum-likelihood estimator, $\hat{\theta}$, is one that, given the sample data, \mathbf{x} , maximizes the log-likelihood function,

$$\hat{\theta} \leftarrow \underset{\theta \in \Theta}{\operatorname{arg\,max}} \ln L_n(\theta | \mathbf{x}) = \underset{\theta \in \Theta}{\operatorname{arg\,max}} \frac{1}{n} \sum_{i=1}^n \ln p(x_i | \theta). \tag{26}$$

The maximum-likelihood estimator is

- a consistent estimator for θ ;
- an asymptotically normal estimator that satisfies the Cramer-Rao lower bound.

Together these statements imply that

$$\sqrt{n}(\hat{\theta} - \theta) \xrightarrow{d} N\left(0, \frac{1}{\mathbb{I}_F \mathbf{X}_{\theta}}\right)$$
 (27)

The proof follows from the asymptotic properties of the score function (cf. PN, §10.4.2), whose Taylor expansion takes the form

$$S(\hat{\theta}|\mathbf{X}) \approx S(\theta|\mathbf{X}) + (\hat{\theta} - \theta) \frac{\partial}{\partial \theta} S(\theta|\mathbf{X}) \Rightarrow \sqrt{n}(\hat{\theta} - \theta) \approx \frac{\frac{1}{\sqrt{n}} S(\theta|\mathbf{X})}{-\frac{1}{n} \frac{\partial}{\partial \theta} S(\theta|\mathbf{X})}$$
(28)

Using the property that the expectation of the score function vanishes, we apply the central limit theorem (cf. PN, §9.2.2) to the numerator,

$$\frac{1}{\sqrt{n}}S(\theta|\mathbf{X}) = \sqrt{n}\left(\frac{1}{n}S(\theta|\mathbf{X}) - \mathbb{E}S(\theta|\mathbf{X})\right) \xrightarrow{d} N(\mathbb{E}S(\theta|\mathbf{X}), \mathbb{V}S(\theta|\mathbf{X})) = N(0, \mathbb{I}_F\mathbf{X}_\theta), \tag{29}$$

we apply the law of large numbers (cf. PN, §9.2.1) to the denominator,

$$-\frac{1}{n}\frac{\partial}{\partial \theta}S(\theta|\mathbf{X}) \xrightarrow{p} -\mathbb{E}\frac{\partial}{\partial \theta}S(\theta|\mathbf{X}) = \mathbb{I}_F \mathbf{X}_{\theta}$$
(30)

and conclude via Slutsky's theorem (cf. PN, §9.1.5) that

$$\sqrt{n}(\hat{\theta} - \theta) \xrightarrow{d} \frac{1}{\mathbb{I}_F \mathbf{X}_{\theta}} N(0, \mathbb{I}_F \mathbf{X}_{\theta}) = N\left(0, \frac{1}{\mathbb{I}_F \mathbf{X}_{\theta}}\right). \tag{31}$$

3.3.3.2 Multidimensional Maximum-Likelihood Estimators

The extension of maximum-likelihood estimation to the multidimensional setting is quite straightforward: the univariate parameter is replaced by a vector, $\theta \to \theta$, the first and second moments of the score function are replaced by vector- and matrix-valued quantities, $\mathbf{0}$ and $\mathbb{I}_F \mathbf{X}_{\theta}$, respectively, and the solution to the extremal equation,

$$\hat{\boldsymbol{\theta}} \leftarrow \arg\max_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} \ln L_n(\boldsymbol{\theta}|\mathbf{x}) = \arg\max_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} \frac{1}{n} \sum_{i=1}^n \ln p(x_i|\boldsymbol{\theta}). \tag{32}$$

The Taylor expansion and asymptotic arguments in (28) – (31) are extended to cover the vector-matrix quantities for first and second moments, with the analogous result for asymptotic normality,

$$\sqrt{n}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}) \stackrel{d}{\longrightarrow} N(\mathbf{0}, (\mathbb{I}_F \mathbf{X}_{\boldsymbol{\theta}})^{-1}).$$
 (33)

3.3.3.3 Numerical Methods for Maximum-Likelihood Estimators

3.3.4 Bayesian Estimators

Bayes Risk

$$\mathbb{E}_{\pi}\Lambda(\theta,\hat{\theta})\tag{34}$$

$$\hat{\theta}^* \leftarrow \max_{\hat{\theta}^* \in \Theta} \mathbb{E}_{\pi} \Lambda(\theta, \hat{\theta}) \tag{35}$$

$$\Lambda(\theta, \hat{\theta}) = (\theta - \hat{\theta})^2 \Rightarrow 0 = \left. \frac{\partial}{\partial \hat{\theta}} \mathbb{E}_{\pi} (\theta - \hat{\theta})^2 \right|_{\hat{\theta} = \hat{\theta}^*} = -2\mathbb{E}_{\pi} (\theta - \hat{\theta}^*) \Rightarrow \hat{\theta}^* = \mathbb{E}_{\pi} \theta \tag{36}$$

Iterative method

$$\pi(\theta) \equiv \pi(\theta|\mathbf{x}) = \frac{p(\mathbf{x}|\theta)\pi(\theta)}{p(\mathbf{x})}$$
 (37)

$$\cdots \mathbf{x}_{i}, \theta_{i} \Rightarrow \hat{\theta}_{i+1} : \mathbf{x}_{i+1}, \theta_{i+1} \Rightarrow \hat{\theta}_{i+2}, \cdots$$
(38)

4 Interval Testing

Following the terminology introduced above in §2.2.1, an **interval test** for a model parameter is a quantitative measure applied to an assertion on point estimates, especially with respect to the range of values in which test statistics might fall.

As described above in §3, the point estimator is derived from an ensemble of points, usually sampled independently, $\mathbf{X} = (X_1, \dots, X_n)$, $X_i \sim X \equiv X | \theta$, and is generated by the statistic, $T(\mathbf{X})$, that varies in a wll-know fashion with the parameter. Here, assertions of the interval estimator are defined through the probability measure that governs the test statistic, $\mathbb{P} \equiv \mathbb{P}_{T(\mathbf{X})}$, so that for any given subset of the parameter space, $\mathcal{A} \subset \Theta$, and any given data sample, $\mathbf{X} = \mathbf{x}$, the interval estimator is evaluated from the quantity,

$$\mathbf{X} = (X_1, \dots, X_n), X_i \sim X \equiv X | \theta \Rightarrow \mathbb{P}\{(T(\mathbf{X}) \in \mathcal{A}) | \mathbf{X} = \mathbf{x}\}.$$
(39)

4.1 Hypothesis Testing and Interval Estimators

4.1.1 Hypotheses

• A hypothesis is an assertion about the model distribution, $X|\theta$, usually with respect to the range in which the key parameter, θ , falls. If the set of possible parameter values, $\theta \in \Theta$, is split into two disjoint sets, Θ_0 and Θ_1 , the complementary null and alternative hypotheses, H_0 and H_1 , are the assertions,

$$\Theta_0 \cup \Theta_1 = \Theta
\Theta_0 \cap \Theta_1 = \emptyset$$
 \Rightarrow
$$\begin{cases}
\text{null hypothesis:} & H_0 : \theta \in \Theta_0 \\
\text{alternative hypothesis:} & H_1 : \theta \in \Theta_1
\end{cases}$$
(40)

• A test statistic is a random variable that is a function of the data sample, $T(\mathbf{X})$. A realization of the test statistic given an observation, \mathbf{x} , is expressed in lower case symbols,

$$t(\mathbf{x}) \equiv T(\mathbf{X})|(\mathbf{X} = \mathbf{x}). \tag{41}$$

The test statistic may be designed to approximate the population parameter, $T(\mathbf{X}) \approx \theta$, or it may take on a range of distributions that vary with the parameter in some planned fashion;

The probability measure associated with the test statistic is parametrized by the population parameter,

$$\mathbb{P} \equiv \mathbb{P}_{T(\mathbf{X})|\theta} \tag{42}$$

• For any given parameter values, θ , only one of the hypotheses, H_0 or H_1 , in (40) can be true. A **rejection region** is a subset of the range of the test statistic, usually a disjoint union of real intervals, $\mathcal{R} \subset \mathbb{R}$, constructed such that membership within is sufficiently improbable as to imply the likely falsity of the null hypothesis:

$$t(\mathbf{x}) \in \mathcal{R}$$
: reject the null hypothesis (43)

$$t(\mathbf{x}) \in \mathcal{R}^C$$
: accept the null hypothesis (44)

• Given a decomposition of the parameter set, Θ , into disjoint subsets, Θ_0 and Θ_1 , we may design a test statistic, $T_{\theta}(\mathbf{X})$, that determines the correct set to which any given parameter value belongs. In this case two kinds of errors may occur, for the two cases in which property and the inference disagree,

Type I error: with probability
$$\mathbb{P}_{\theta \mid \theta \in \Theta_0} \{ t(\mathbf{x}) \in \mathcal{R} \} \Rightarrow \theta \in \Theta_0 \text{ and } t(\mathbf{x}) \in \mathcal{R}$$
 (45)

Type II error: with probability
$$\mathbb{P}_{\theta|\theta\in\Theta_1}\{t(\mathbf{x})\in\mathcal{R}^C\}\Rightarrow\theta\in\Theta_1 \text{ and } t(\mathbf{x})\in\mathcal{R}^C$$
 (46)

• The **power function** of a hypothesis test shows the correctness of the inference:

$$\beta(\theta) = \mathbb{P}_{\theta \mid \theta \in \Theta_0} \{ t(\mathbf{x}) \in \mathcal{R} \} = 1 - \mathbb{P}_{\theta \mid \theta \in \Theta_1} \{ t(\mathbf{x}) \in \mathcal{R}^C \}. \tag{47}$$

The power function is sharpest when there are no errors for any underlying parameter,

$$\beta(\theta) = \begin{cases} 0 \text{ for all } \theta \in \Theta_0 \\ 1 \text{ for all } \theta \in \Theta_1 \end{cases}$$
(48)

• A level- α test for a hypothesis test is for which the power function is bounded when the null hypothesis is true:

$$\underset{\theta \in \Theta_0}{\arg \max} \beta(\theta) \le \alpha, \quad 0 \le \alpha \le 1. \tag{49}$$

• Designate the set of all level- α test as \mathcal{C}_{α} . The **uniformly most powerful test** level- α test is one, $\beta \in \mathcal{C}_{\alpha}$, such that for any other level- α test, $\beta' \neq \beta, \beta' \in \mathcal{C}_{\alpha}$,

$$\beta(\theta) \ge \beta'(\theta) \text{ for all } \theta \in \Theta_1.$$
 (50)

• A **p-value** is a test statistic, $p(\mathbf{X})$, whose realized values are bounded within the range of cumulative probabilities, $0 \le p(\mathbf{X}) \le 1$. A *p*-value is *valid*, provided that

$$\mathbb{P}_{\theta \mid \theta \in \Theta_0} \{ p(\mathbf{x} \le \alpha) \} \le \alpha. \tag{51}$$

If the same bound applies to the test statistic and the probability measure that it generates, then the valid p-test serves as a level- α test. Small p-values, $p(\mathbf{x}) \leq \alpha \ll 1$, imply that the alternative hypothesis, H_1 , is the correct one.

The skill in hypothesis test design is, given the parametrized model distribution, $X|\theta$, to craft the test statistic, $T(\mathbf{X})$, and acceptance region, \mathcal{R} , so that the resulting power function is sharp. It is common to use p-values as test statistics, and acceptance regions defined by the tails of the distribution.

4.1.2 Interval Tests

An interval estimator for a population parameter, θ , is a pair of test statistics, $A(\mathbf{X})$ and $B(\mathbf{X})$, such that one dominates the other, $A(\mathbf{x}) \leq B(\mathbf{x})$, for all samples, \mathbf{x} . The test statistics are selected to serve as bounds on the parameter, $A(\mathbf{x}) \leq \theta \leq B(\mathbf{x})$.

• The **coverage probability** for an interval test is probability that the population parameter falls within the bounds,

$$\mathbb{P}_{\theta}\{\theta \in [A(\mathbf{x}), B(\mathbf{x})]\}; \tag{52}$$

 The confidence coefficient is the smallest coverage probability over all population parameters for a given data sample,

$$\underset{\theta}{\arg\min} \, \mathbb{P}_{\theta} \{ \theta \in [A(\mathbf{x}), B(\mathbf{x})] \}; \tag{53}$$

• A confidence interval is an interval estimator endowed with a confidence coefficient.

The confidence interval is a kind of hypothesis test: any given acceptance region – a set in the sample space – can be matched to a interval estimator defined in the parameter space. The function pair, $A(\mathbf{X})$ and $B(\mathbf{X})$, can be expressed as p-value – frequently in terms of their union – and interpreted as probability measures.

5 Statistical Tests

5.1 Common Interval Tests Based on Likelihood Functions

Three common interval tests for parametrized models, $X|\theta$, are derived from the likelihood function:

- Likelihood Ratio Test
- Wald Test
- Score Test

As with all interval tests, the null and alternative hypotheses are defined in terms of parameter membership in one of two disjoint sets, *i.e.*, $\theta \in \Theta$, for which $\Theta = \Theta_0 \cup \Theta_1$ and $\emptyset = \Theta_0 \cap \Theta_1$, so that

null hypothesis:
$$H_0: \theta \in \Theta_0$$
 (54)

alternative hypothesis:
$$H_1: \theta \in \Theta_1$$
 (55)

All three tests are designed for **single-point hypotheses** – the case for which $\Theta_0 = \{\theta_0\}$. Here, the three tests differ in the computational burden placed on likelihood functions: the Wald test requires information only at the global maximum, the score test requires information only at the hypothesized value, while the likelihood ratio test requires the evaluation at both.

The key insight behind all three tests is identical: should the null hypothesis be correct, then the maximum-likelihood estimator based on randomly sampled data would be close by, for which distance is measured in probabilistic terms. Although the details of each test differ for finite samples – and conclusions may differ in edge cases – asymptotically, all converge to the chi-square distribution.

Whereas the Wald and score tests handle only single-point hypotheses, the likelihood ratio test can be worked into the more general setting in which the null value falls within a specified range.

5.1.1 Likelihood Ratio Test

The likelihood ratio test is an interval test for a population parameter, $\theta \in \Theta$, given a model distribution, $X|\theta$. The test statistic for the likelihood ratio scales the likelihood of a proposed value, θ_0 , or maximum of a set of values, against the *global* maximum, $\hat{\theta}$, which ensures the interpretion of the test statistic as a cumulative propability distribution. The test leverages well-known properties of likelihood functions, score functions and Fisher information (again, *cf. PN*, §10) to generate the machinery of the interval testing – such as rejection regions, level- α sets and probability measures – as well as to ensure the asymptotic normality of the estimator.

The hypothesized values of the population parameter for the model distribution might fall in one of two disjoint sets,

null hypothesis:
$$H_0: \theta \in \Theta_0$$
 (56)

alternative hypothesis:
$$H_1: \theta \in \Theta_1$$
 (57)

Given the random variable for data sampled identically and independently from the common model distribution, $\mathbf{X} = (X_1, \dots, X_n)$, the test statistic is formed from the ratio of likelihoods, one taken as the restricted maximizer of the set that comprises the null hypothesis, $\theta \in \Theta_0$, and the other as the global maximizer over all parameters, $\theta \in \Theta$,

$$\lambda(\mathbf{X}) = \frac{\underset{\theta \in \Theta_0}{\arg \max} L(\theta | \mathbf{X})}{\underset{\theta \in \Theta}{\arg \max} L(\theta | \mathbf{X})}.$$
 (58)

For any given data sample, \mathbf{x} , the likelihood function has a single global maximum, with curvature that is everywhere positive. The likelihood ratio test therefore takes unit value at the global maximizer, $\theta_0 = \hat{\theta}$, and 'high values' at positions close by. The likelihood ratio test links a distance metric to probabilities generated by random sampling, which justifies acceptance or rejection of the asserted hypothesis.

- The range of the likelihood ratio is the unit interval, $0 \le \lambda(\mathbf{x}) \le 1$, and the null hypothesis is satisfied precisely at the endpoint, $\lambda = 1$;
- The null hypothesis is supported by sample data that lie in sets close to the global maximum, which is codified in rejection sets defined by threshold values, $0 \le c \le 1$,

$$\mathcal{R} = \{ \mathbf{x} \in \mathbb{R}^n : \lambda(\mathbf{x}) \le c \}; \tag{59}$$

• Given the probability measure, \mathbb{P}_{θ} , generated by the test statistic, the level- α test is specified by choosing the threshold, c, such that

$$\underset{\theta \in \Theta_0}{\arg \min} \mathbb{P}_{\theta} \{ \lambda(\mathbf{x}) \le c \} = \alpha. \tag{60}$$

Since the threshold, c, is itself an element of the unit interval, the likelihood ratio is a p-value;

• The curvature of the likelihood function is positive everywhere, and provided by the Fisher information, $\mathbb{I}_F X_\theta$, at the maximal point. The curvature at nearby points is approximately the same, and can be used to estimate the probability that the most-likely parameter values estimated from randomly generated data points differ from the true maximum value.

The special case of the **single-point hypothesis** occurs when the null hypothesis consists of a single value,

$$\Theta_0 = \{\theta_0\},\tag{61}$$

for which the likelihoods of the restricted and global maximizers are given by

restricted maximizer:
$$\theta_0$$
 global maximizer: $\hat{\theta}$ $\Rightarrow \lambda(\mathbf{X}) = \frac{L(\theta_0|\mathbf{X})}{L(\hat{\theta}|\mathbf{X})}$ (62)

The asymptotic properties of the single-point hypothesis test are derived from a Taylor expansion of the likelihood in the numerator about the global maximum, for which the logarithm of the result, truncated to the second-order term, is the product,

$$-2\ln\lambda(\mathbf{X}) \approx -2\left(\ln L(\hat{\theta}|\mathbf{X}) - \ln L(\hat{\theta}|\mathbf{X}) + (\theta_0 - \hat{\theta})S(\hat{\theta}|\mathbf{X}) + \frac{1}{2}(\theta_0 - \hat{\theta})^2 \frac{\partial}{\partial \theta}S(\hat{\theta}|\mathbf{X})\right)$$

$$\approx -(\theta_0 - \hat{\theta})^2 \frac{\partial}{\partial \theta}S(\hat{\theta}|\mathbf{X}).$$
(63)

The derivation of the asymptotic distribution follows the same arguments as presented above in §3.3.3 for maximum-likelihood point estimators, since we have

$$\frac{-\frac{1}{n}\frac{\partial}{\partial\theta}S(\hat{\theta}|\mathbf{X}) \stackrel{p}{\longrightarrow} \mathbb{I}_{F}\mathbf{X}_{\theta}}{\sqrt{n}(\theta_{0} - \hat{\theta}) \stackrel{d}{\longrightarrow} N\left(0, \frac{1}{\mathbb{I}_{F}\mathbf{X}_{\theta}}\right)} \right\} \Rightarrow \sqrt{n}(\theta_{0} - \hat{\theta})\sqrt{-\frac{1}{n}\frac{\partial}{\partial\theta}S(\hat{\theta}|\mathbf{X})} \stackrel{d}{\longrightarrow} N(0, 1)$$
(64)

The logarithm of the likelihood ratio is the square of the result in (64), so that we immediately derive the chi-square distribution in the asymptotic limit,

$$-2\ln\lambda(\mathbf{X}) \approx -(\theta_0 - \hat{\theta})^2 \frac{\partial}{\partial \theta} S(\hat{\theta}|\mathbf{X}) = \left(\sqrt{n}(\theta_0 - \hat{\theta})\sqrt{-\frac{1}{n}\frac{\partial}{\partial \theta} S(\hat{\theta}|\mathbf{X})}\right)^2 \xrightarrow{d} \chi^2.$$
 (65)

5.1.2 Wald Test

The Wald Test is an interval test for the single-point hypothesis formed from the ratio of the square distance between hypothesized and maximum values, and the variance of the global estimator,

$$\frac{(\theta_0 - \hat{\theta})^2}{\mathbb{V}\hat{\theta}}.\tag{66}$$

The asymptotic limit of these quantities can be derived from quantities expressed above in §§3.3.3.1 & 5.1.1. Assuming that the null hypothesis holds – the restricted maximizer, θ_0 , is the true parameter value – then we have

$$\left. \begin{array}{l} \mathbb{V}\hat{\theta} \approx \frac{1}{n} \frac{1}{\mathbb{I}_{F} \mathbf{X}_{\theta}} \\ \sqrt{n}(\theta_{0} - \hat{\theta}) \stackrel{d}{\longrightarrow} \mathrm{N}(0, \frac{1}{\mathbb{I}_{F} \mathbf{X}_{\theta}}) \end{array} \right\} \Rightarrow \frac{(\theta_{0} - \hat{\theta})^{2}}{\mathbb{V}\hat{\theta}} \approx \left(\sqrt{\mathbb{I}_{F} \mathbf{X}_{\theta}} \sqrt{n}(\theta_{0} - \hat{\theta}) \right)^{2} \stackrel{d}{\longrightarrow} \chi^{2}. \tag{67}$$

Note that the Wald test only requires quantities evaluated at the unrestricted global maximum, θ .

5.1.3 Score Test

The **Score Test** is an interval test for the single-point hypothesis formed from the ratio of the square of the score function evaluated at the hypothesized value and the Fisher information,

$$\frac{S(\theta_0|\mathbf{X})^2}{\mathbb{I}_F \mathbf{X}_{\theta}}. (68)$$

The asymptotic limit of these quantities is derived directly from the mean and variance of the score function, so that

$$\mathbb{E}S(\theta_0|\mathbf{X}) = 0 \\
\mathbb{V}S(\theta_0|\mathbf{X}) = \mathbb{I}_F \mathbf{X}_{\theta}$$

$$\Rightarrow \frac{S(\theta_0|\mathbf{X})^2}{\mathbb{I}_F \mathbf{X}_{\theta}} = \left(\frac{1}{\sqrt{\mathbb{I}_F \mathbf{X}_{\theta}}} S(\theta_0|\mathbf{X})\right)^2 \xrightarrow{d} \chi^2$$
(69)

Note that the score test only requires quantities evaluated at the null parameter, θ_0 .

5.1.4 The Nevman-Pearson Lemma and Uniformly Most Powerful Tests

The Neyman-Pearson Lemma

5.2 Standard Tests

5.2.1 Discrete Models

5.2.1.1 Mean Frequencies of Multinomial Models: Pearson's Chi-square Test

The multinomial distribution (cf. PN, §7.1.1.6) is realized by the sum of n repeated, independent, composite Bernoulli trials for which the k possible different outcomes are defined by the mean probability vector,

$$\mathbf{p} = (p_1, \dots, p_k)^{\top}, \quad \sum_{i=1}^{k} p_i = 1,$$
 (70)

and covariance matrix

$$\Sigma = \begin{pmatrix} p_{1}(1-p_{1}) & \cdots & -p_{1}p_{i} & \cdots & -p_{1}p_{k} \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ -p_{1}p_{i} & \cdots & p_{i}(1-p_{i}) & \cdots & -p_{i}p_{k} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -p_{1}p_{k} & \cdots & -p_{i}p_{k} & \cdots & p_{k}(1-p_{k}) \end{pmatrix}.$$
(71)

We can represent the random variable for each draw as the vector,

$$\mathbf{X} = (X_1, \cdots, X_k),\tag{72}$$

for which one of the coordinate random variables takes unit value, and the remaining coordinate random variables take zero value, on any given draw. For an independent sequence of draws we can represent the i^{th} coordinate by superscript and the random variable given n draws as the vector,

$$\mathbf{X}^{n} = \left(\sum_{i=1}^{n} X_{1}^{i}, \cdots, \sum_{i=1}^{n} X_{k}^{i}\right). \tag{73}$$

The random variable for the sample mean is constructed by normalizing each coordinate by the total number of draws, for which the mean vector and covariance matrix are immediately derived,

$$\bar{\mathbf{X}}^{n} = \left(\frac{1}{n}\sum_{i=1}^{n} X_{1}^{i}, \cdots, \frac{1}{n}\sum_{i=1}^{n} X_{k}^{i}\right) \Rightarrow \begin{cases} \mathbb{E}\bar{\mathbf{X}}^{n} = \mathbf{p} \\ \mathbb{C}(\bar{\mathbf{X}}^{n}\bar{\mathbf{X}}^{n\top}) = \frac{1}{n}\mathbf{\Sigma} \end{cases}$$
(74)

and by applying the central limit theorem we derive the asymptotic distribution of the sample mean vector,

$$\sqrt{n}(\bar{\mathbf{X}}_n - \mathbf{p}) \xrightarrow{d} \mathrm{N}(0, \Sigma).$$
 (75)

The covariance matrix, Σ , is singular, due to the dependence among coordinate random variables. In fact by pre- and post-multiplying the covariance matrix by a diagonal matrix formed from the mean vector,

$$\Gamma = \operatorname{diag}(\mathbf{p}) \Rightarrow \Gamma^{-\frac{1}{2}} \mathbf{\Sigma} \Gamma^{-\frac{1}{2}} = I_k - \mathbf{p}^{\frac{1}{2}} \mathbf{p}^{\frac{\top}{2}}, \tag{76}$$

we construct a projection matrix of rank (k-1) (cf. LAN, §3.11), since the dyad, $\mathbf{p}^{\frac{1}{2}}\mathbf{p}^{\frac{\top}{2}}$, is a rank-1 adjustment to the k-dimensional identity matrix. Since linear transformations of Gaussian random

variables are also Gaussian, the linearly transformed, scaled sample mean vector is a kind of defective standard multivariate normal distribution over (k-1) dimensions,

$$\sqrt{n}\Gamma^{-\frac{1}{2}}(\bar{\mathbf{X}}_n - \mathbf{p}) \stackrel{d}{\longrightarrow} \mathcal{N}(0, \Gamma^{-\frac{1}{2}}\mathbf{\Sigma}\Gamma^{-\frac{1}{2}}).$$
(77)

Since it is always possible to rotate the coordinate system to align with the (k-1) eigenvectors of the projection matrix, we derive the limiting distribution of the inner product as chi-square with (k-1) degrees of freedom:

$$\sum_{i=1}^{k} \frac{(x_i - np_i)^2}{np_i} = \left(\sqrt{n}\Gamma^{-\frac{1}{2}}(\bar{\mathbf{X}}_n - \mathbf{p})\right)^{\top} \left(\sqrt{n}\Gamma^{-\frac{1}{2}}(\bar{\mathbf{X}}_n - \mathbf{p})\right) \xrightarrow{d} \chi_{k-1}^2.$$
 (78)

5.2.1.2 Mean Frequencies of Multinomial Models: Fisher's Exact Test

5.2.2 Continuous Models

5.2.2.1 Mean of Gaussian Model: T-test

The **T-Test** is an interval test for the single-point hypothesis that a set of data points is drawn, independently and identically, from a Gaussian distribution with mean, μ_0 : if the population mean is represented as the parameter, μ , the null and alternative hypotheses can be represented as,

$$H_0: \mu = \mu_0 \tag{79}$$

$$H_1: \mu \neq \mu_0 \tag{80}$$

Although it is possible to express the test directly in terms of the likelihood ratio, it is more common, and more insightful, to construct the test statistic directly from the sample moments.

Given that the true population mean and variance, μ and σ^2 , are unknown, we model the randomly sampled data points by the joint random vector,

$$X_i \sim \mathrm{N}(\mu, \sigma^2) \Rightarrow \mathbf{X} = (X_i, \cdots, X_n)^{\top} \sim \mathrm{N}(\mu \mathbf{1}_n, \sigma^2 \mathbf{I}_n).$$
 (81)

The test statistic is formed from the ratio of sample mean to sample standard deviation, each of which depends on the unknown population parameters. Here, the numerator is distributed as standard normal, the square of the denominator is distributed as chi square, and it follows that the ratio of the two, which is independent of the population variance, is distributed as a Student T random variable ($cf. PN, \S7.2.4.2$):

$$\hat{\mu} = \frac{1}{n} \sum_{i=1}^{n} X_{i} \Rightarrow \sqrt{n} \frac{\hat{\mu} - \mu}{\sigma} \sim \mathcal{N}(0, 1)$$

$$\hat{\sigma}^{2} = \frac{1}{n-1} \sum_{i=1}^{n} (X_{i} - \hat{\mu})^{2} \Rightarrow \frac{\hat{\sigma}^{2}}{\sigma^{2}/(n-1)} \sim \chi^{2}$$

$$\Rightarrow T(\mathbf{X}) \equiv \frac{\hat{\mu} - \mu_{0}}{\hat{\sigma}/\sqrt{n}} \sim T_{n-1}$$
(82)

The confidence intervals are constructed so that the upper and lower ranges of the test statistic, symmetrically arranged about zero, [-c, c], are chosen so that the probability that the data points are randomly sampled from a Gaussian distribution that satisfies the null hypothesis is equal to the demanded level, α ,

$$\mathbb{P}\{-c < T_{n-1}(\mathbf{X}) < c\} = \alpha. \tag{83}$$

5.2.2.2 Common Means of Multiple Gaussian Models: F-Test

The **F-Test** is an interval test for the hypothesis that distinct sets of data points – termed 'treatments' –

are drawn, independently and identically, from a single Gaussian distribution. The F-Test is a standard part of model comparison which addresses the statistical distinction of different treatments, usually from a random basis. If the k treatments for a given response are modeled as the Gaussian random variables,

$$X_i \sim \mathcal{N}(\mu_i, \sigma^2), 1 \le i \le k, \tag{84}$$

all of which share a common variance, σ^2 , then the null and alternative hypotheses take the form,

$$H_0: \mu_1 = \dots = \mu_k \equiv \mu \tag{85}$$

$$H_1: \mu_i \neq \mu_j$$
, for some $i \neq j$ (86)

As with the T-Test above, it is possible to express the test directly in terms of the likelihood ratio. It is more insightful, however, to ground the quantities in terms commonly used in the statistical evaluation of models, and prove independence by linear algebraic methods. In other words the F-Test is most clearly derived as the consequence of an extended Fisher's Theorem (cf. PN, §7.3.1.5).

We assume that there k treatments in all, each with n_i measurements, and a total of N measurements,

total number of points in each treatment:
$$n_i, 1 \le i \le k$$
 (87)

total number of points in all treatments:
$$N = \sum_{i=1}^{k} n_i$$
 (88)

for which the sample response data points are organized by treatment,

$$x_{ij} \Rightarrow \begin{cases} i : \text{treatment index} \\ j : \text{measurement index} \end{cases}$$
 (89)

The null hypothesis is equivalent to the assertion that the response variables can be treated uniformly,

$$\mathbf{x} = (x_{1,1}, \cdots, x_{1,n_1}, x_{2,1}, \cdots, x_{k-1,n_{k-1}}, x_{k,1}, \cdots, x_{k,n_k}),$$
(90)

and that the joint distribution is the product of IID marginals.

$$X_i \sim X \sim N(\mu, \sigma^2) \Rightarrow \mathbf{X} \sim N(\mu \mathbf{1}_N, \sigma^2 \mathbf{I}_N).$$
 (91)

The standard test is defined in terms of two kinds of 'group' variability measures, one of which covers the variability of means across treatments, and the second the variability of measurements within a treatment. Defining the various sample means as

$$\hat{\mu}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{ij}, 1 \le i \le k \tag{92}$$

$$\hat{\mu} = \frac{1}{N} \sum_{i=1}^{k} \sum_{j=1}^{n_i} x_{ij} \tag{93}$$

the statistical test is covered by the assertion,

between-group variability:
$$\frac{1}{k-1} \sum_{i=1}^{k} n_i (\hat{\mu}_i - \hat{\mu})^2$$
within-group variability:
$$\frac{1}{N-k} \sum_{i=1}^{k} \sum_{j=1}^{n_i} (x_{ij} - \hat{\mu}_i)^2$$

$$\Rightarrow T(\mathbf{X}) = \frac{\text{between-group variability}}{\text{within-group variability}} \sim F_{k-1,N-k}. \quad (94)$$

The outline of the derivation of the standard test is as follows:

- Invoke Fisher's theorem on the joint distribution, which partitions the vector space into orthogonal subspaces:
 - A 1-dimensional subspace that contains information on the overall mean;
 - \circ A (N-1)-dimensional subspace that contains information on the overall variance;
- Further partition the variance subspace into two orthogonal subspaces:
 - \circ A (k-1)-dimensional subspace that covers the between-group contribution to variance;
 - \circ A (N-k)-dimensional subspace that covers the within-group contribution to variance;
- Manipulate the joint Gaussian pdf:
 - Factor contributions in the argument of the Gaussian exponential into Gaussian products;
 - Rotate the coordinate system, via orthogonal transformation, to align with the vector subspaces;
 - Independence of within- and between-group variability shown by factored pdf;
- Express both within- and between-group variability as weighted sums of chi-square distributed random variables, whose ratio is immediately F-distributed.

We start by introducing linear algebraic quantities – partial ones vectors and identity matrices – that help extract sample data for the i^{th} treatment from the joint vector in (90),

$$\mathbf{1}_{[a_i,b_i]} \equiv \mathbf{1}_{[i]} \Rightarrow l^{th} \text{ entry:} \begin{cases} 1, & \text{if } 1 \leq a_i \leq l \leq b_i \leq N \\ 0, & \text{otherwise} \end{cases}$$

$$\mathbf{I}_{[a_i,b_i]} \equiv \mathbf{I}_{[i]} \Rightarrow (l,m)^{th} \text{ entry:} \begin{cases} 1 & \text{if } 1 \leq a_i \leq l \leq b_i \leq N \\ 0, & \text{otherwise} \end{cases}$$

$$(95)$$

$$\mathbf{I}_{[a_i,b_i]} \equiv \mathbf{I}_{[i]} \Rightarrow (l,m)^{th} \text{ entry: } \begin{cases} 1 \text{ if } 1 \le a_i \le l = m \le b_i \le N \\ 0, \text{ otherwise} \end{cases}$$
 (96)

Taking care to align the vector and matrix intervals with the treatment ranges,

$$\begin{vmatrix}
a_i = 1 + \sum_{l=1}^{i-1} n_l \\
b_i = \sum_{l=1}^{i} n_l
\end{vmatrix} \Rightarrow \begin{cases}
\mathbf{1}_N = \sum_{i=1}^{k} \mathbf{1}_{[a_i, b_i]} \equiv \sum_{i=1}^{k} \mathbf{1}_{[i]} \\
\mathbf{I}_N = \sum_{i=1}^{k} \mathbf{I}_{[a_i, b_i]} \equiv \sum_{i=1}^{k} \mathbf{I}_{[i]}
\end{vmatrix}$$
(97)

the treatment and total means are expressed in terms of the appropriate projection matrices.

$$\hat{\mu}_{i} \mathbf{1}_{[i]} = \mathbf{1}_{[i]} \frac{1}{n_{i}} \mathbf{1}_{[i]}^{\top} \mathbf{x} = \mathbf{1}_{[i]} (\mathbf{1}_{[i]}^{\top} \mathbf{1}_{[i]})^{-1} \mathbf{1}_{[i]}^{\top} \mathbf{x} = P_{\mathbf{1}_{[i]}} \mathbf{x}$$
(98)

$$\hat{\mu} \mathbf{1}_N = \mathbf{1}_N \frac{1}{N} \mathbf{1}_N^\top \mathbf{x} = \mathbf{1}_N (\mathbf{1}_N^\top \mathbf{1}_N)^{-1} \mathbf{1}_N^\top \mathbf{x} = P_{\mathbf{1}_N} \mathbf{x}$$
(99)

Fisher's theorem asserts that the N-dimensional vector space, \mathbb{R}^N , which is the domain of the sample data, $\mathbf{x} \in \mathbb{R}^N$, is composed of two orthogonal subspaces,

Vector subspace for the mean:
$$\operatorname{Im}(P_{\mathbf{1}_N})$$

Vector subspace for the variance: $\operatorname{Im}(\mathbf{I}_N - P_{\mathbf{1}_N})$ $\Rightarrow \mathbb{R}^N = \operatorname{Im}(P_{\mathbf{1}_N}) \oplus \operatorname{Im}(\mathbf{I}_N - P_{\mathbf{1}_N}).$ (100)

The F-Test is based on a further decomposition of the variance subspace into two orthogonal subspaces,

$$\operatorname{Im}(\mathbf{I}_{N} - P_{\mathbf{1}_{N}}) = \operatorname{Im}(\mathbf{I}_{N} - \sum_{i=1}^{k} P_{\mathbf{1}_{[i]}}) \oplus \operatorname{Im}(\sum_{i=1}^{k} P_{\mathbf{1}_{[i]}} - P_{\mathbf{1}_{N}}), \tag{101}$$

one of which contains information on within-group and the other on between-group variance.

In fact using linear algebraic notation, the within-group variability is expressed as

$$\frac{1}{N-k} \sum_{i=1}^{k} \sum_{j=1}^{n_i} (x_{ij} - \hat{\mu}_i)^2 = \frac{1}{N-k} \sum_{i=1}^{k} \mathbf{x}^{\top} (\mathbf{I}_{[i]} - P_{\mathbf{1}_{[i]}})^{\top} (\mathbf{I}_{[i]} - P_{\mathbf{1}_{[i]}}) \mathbf{x}$$

$$= \frac{1}{N-k} \mathbf{x}^{\top} \left(\sum_{i=1}^{k} (\mathbf{I}_{[i]} - P_{\mathbf{1}_{[i]}}) \right) \mathbf{x}$$

$$= \frac{1}{N-k} \mathbf{x}^{\top} \left(\mathbf{I}_{N} - \sum_{i=1}^{k} P_{\mathbf{1}_{[i]}} \right) \mathbf{x}$$
(102)

while the between-group variability is given by

Orthogonality of these subspaces follows from direct calculation of the projection operators,

$$\left(\sum_{i=1}^{k} P_{\mathbf{1}_{[i]}}\right) \left(\sum_{i=1}^{k} P_{\mathbf{1}_{[i]}}\right) = \sum_{i=1}^{k} P_{\mathbf{1}_{[i]}}
\left(\sum_{i=1}^{k} P_{\mathbf{1}_{[i]}}\right) P_{\mathbf{1}_{N}} = P_{\mathbf{1}_{N}}$$

$$\Rightarrow \left(\mathbf{I}_{N} - \sum_{i=1}^{k} P_{\mathbf{1}_{[i]}}\right) \left(\sum_{i=1}^{k} P_{\mathbf{1}_{[i]}} - P_{\mathbf{1}_{N}}\right) = \mathbf{0}. \tag{104}$$

Rotating the coordinate system and factoring the Gaussian distributions into contributions that align perfectly with the orthogonal subspaces is a straightforward task. The result is that each coordinate contributes independently a single degree of freedom to a collective chi-square distribution, so that we have

$$\frac{1}{\sigma^2} \mathbf{x}^{\top} \left(\mathbf{I}_N - \sum_{i=1}^k P_{\mathbf{1}_{[i]}} \right) \mathbf{x} = \sum_{j=2}^k \frac{y_j^2}{\sigma^2} \sim \chi_{k-1}^2$$
(105)

$$\frac{1}{\sigma^2} \mathbf{x}^{\top} \left(\sum_{i=1}^k P_{\mathbf{1}_{[i]}} - P_{\mathbf{1}_N} \right) \mathbf{x} = \sum_{j=k}^N \frac{y_j^2}{\sigma^2} \sim \chi_{N-k}^2$$
 (106)

The ratio of between-group to within-group variance is the weighted sum of chi-square distributions, which follows an F-distribution,

$$\frac{U \sim \chi_p^2}{V \sim \chi_q^2} \right\} \Rightarrow W = \frac{U/p}{V/q} \sim F_{p,q}.$$
 (107)

The confidence intervals are constructed so that the upper and lower ranges of the test statistic, symmetrically arranged about zero, [-c, c], are chosen so that the probability that the data points are randomly

sampled from a Gaussian distribution that satisfies the null hypothesis is equal to the demanded level, α ,

$$\mathbb{P}\{-c \le F_{k-1,N-k}(\mathbf{X}) < c\} = \alpha. \tag{108}$$
